#### 1. Introduction 32

Recent decades have seen fierce competition in local and global 33 34 markets, forcing manufacturing enterprises to streamline their lo-35 gistic systems, as they constitute over 30% of the cost of goods sold 36 for many products (Thomas & Griffin, 1996). The major compo-37 nents of logistic costs are transportation costs, representing 38 approximately one third, and inventory costs, representing one 39 fifth (Buffa & Munn, 1989). The transportation and inventory cost reduction problems have been thoroughly studied separately; 40 while, the integrated problem has recently attracted more interest 41 in the research community as new ideas of centralized supply 42 chain management systems, such as vendor managed inventory 43 44 (VMI), have gained acceptance in many supply chain environments. 45

The integration of transportation and inventory decisions is 46 represented in the literature by a general class of problems re-47 48 ferred to as dynamic routing and inventory (DRAI) problems. As defined by Baita, Ukovich, Pesenti, and Favaretto (1998), this 49 class of problems is "characterized by the simultaneous vehicle 50 routing and inventory decisions that are present in a dynamic 51 52 framework such that earlier decisions influence later decisions." 53 They classify the approaches used for DRAI problems into two categories. The first category operates in the frequency domain 54 where the decision variables are replenishment frequencies, or 55

# ABSTRACT

We study an inventory-routing problem in which multiperiod inventory holding, backlogging, and vehicle routing decisions are to be taken for a set of customers who receive units of a single item from a depot with infinite supply. We consider a case in which the demand at each customer is deterministic and relatively small compared to the vehicle capacity, and the customers are located closely such that a consolidated shipping strategy is appropriate. We develop constructive and improvement heuristics to obtain an approximate solution for this NP-hard problem and demonstrate their effectiveness through computational experiments.

headways between shipments. Examples in the literature include the work of Blumenfeld, Burns, Diltz, and Daganzo (1985), Hall (1985), Daganzo (1987), and Ernst and Pyke (1993) (for more references see Daganzo, 1999). Anily and Federgruen (1990) introduced the idea of fixed-partition policies (FPPs) for solving the frequency-domain DRAI problems. FPPs are policies that solve the problem by partitioning the set of customers into a number of regions such that each region is served separately and independently from all other regions. In addition to that, whenever a customer in a partition is visited, all other customers in that partition are visited by the same vehicle. The solution is considered optimal in the set that includes all the FPPs if, with respect to vehicle capacities, it defines regions that minimize the average of the sum of inventory holding costs and transportation costs. Examples in the literature include Anily and Federgruen (1993), Bramel and Simchi Levi (1995). However, Hall (1992) points out that the FPPs approach can not model the case in which deliveries are coordinated. As a consequence, the results it provides are either valid only in the case of independent deliveries, or can be just considered as providing upper bounds for real costs.

The second category, referred to as the time domain approach, determines the schedule of shipments. With discrete time models, quantities and routes are decided at fixed time intervals. Within this category the most famous problem is the inventory routing problem (IRP), which arises in the application of the distribution of industrial gases. The main concern for this kind of application is to maintain an adequate level of inventory for all customers and to avoid any stockout. In the IRP, it is assumed 84 that each customer has a fixed demand rate and the focus is on 85

minimizing the total transportation cost; while inventory costs are mostly not of concern. Examples of this application in the literature include Bell, Dalberto, Fisher, and Greenfield (1983), Golden, Assad, and Dahl (1984), Dror, Ball, and Golden (1985), Dror and Ball (1987), Campbell, Clarke, and Savelsbergh (2002) and Adelman (2003).

92 In this paper, we consider a DRAI problem that addresses the 93 integrated inventory and vehicle routing decisions in the time 94 domain at the operational planning level. This problem, referred to as the inventory-routing problem with backlogging (IRPB), 95 considers multiple planning periods, both inventory and trans-96 97 portation costs, and a situation in which backorders are permitted. The kind of application that permits backorders is, of 98 course, different from the distribution of industrial gases, where 99 100 stockout is not allowed. The proposed model is suitable to 101 industrial applications in which a manufacturer distributes its 102 product to geographically disbursed factories/retailers which 103 are located in cities close to its warehouse. At the operational planning level, backorder decisions are generally justified in 104 two cases. The first is when there is a transportation cost sav-105 106 ing that is higher than the incurred shortage cost by a cus-107 tomer. The second case is when there is insufficient vehicle capacity to deliver to a customer given that renting additional 108 vehicles is not an option due to technological or economic 109 110 constraints.

111 In the literature, the integration of vehicle routing and inven-112 tory decisions with the consideration of inventory costs in the time domain approaches of the DRAI problems has taken different 113 forms. In a few cases a single period planning problem has been 114 115 addressed as found in Federgruen and Zipkin (1984) and Chien, 116 Balakrishnan, and Wong (1989). In the multi-period problem, the decisions are conducted for a specific number of planning 117 periods, or the problem is reduced to a single period problem 118 119 by considering the effect of the long term decisions on the short 120 term ones. Examples include Dror and Ball (1987), Trudeau and 121 Dror (1992), Viswanathan and Mathur (1997), and Herer and Levy 122 (1997).

123 Other researchers take into consideration various forms such 124 as distributing perishable products (Federgruen, Prastacos, & 125 Zipkin, 1986), and the consideration of the time value of money 126 for long-term planning (Dror & Trudeau, 1996). Some work focused on different structures of the distribution network such 127 as Bard, Huang, Jaillet, and Dror (1998) in the case of satellite 128 129 facilities, Chan and Simchi-Levi (1998) in the case where warehouses act as transshipment points in a 3-level distribution net-130 131 work, and Hwang (1999and 2000) in the case of a multi-depot 132 problem.

133 Solution heuristics that have been proposed in the literature for 134 the different variations of the inventory routing problem are either 135 based on subgradient optimization of a Lagrangian relaxation (see 136 Bell et al., 1983 and Chien et al., 1989) or constructive and improvement heuristics. The constructive heuristics are broadly 137 classified into heuristics that allocate customers to service days 138 and then solve a VRP to generate vehicle routes for each day (Dror 139 140 & Ball, 1987); and heuristics that allocate customers to days and vehicles and then solve a traveling salesman problem for every 141 142 assignment (Dror et al., 1985). Improvement heuristics found in the literature (Dror & Levy, 1986 and Federgruen & Zipkin, 1984 143 in the single period case) are generally considered as extensions 144 145 to the arc-exchange and node-exchange heuristics as found in 146 the vehicle routing literature.

147 In the literature of the time domain approaches of the DRAI 148 problems, some models in the case of multi-period planning 149 may include shortage or stockout costs; however, backorder 150 decisions are generally not explicitly considered. Instead, the 151 shortage or stock-out cost is treated as the penalty cost that is incurred due to making direct deliveries to customers whose demand is not fulfilled in the regular delivery route in a given period. Examples of such models in the literature include Herer and Levy (1997) and Jaillet, Bard, Huang, and Dror (2002). In this paper, we consider a situation in which backorder decisions are either unavoidable or more economical, and they have to be coordinated with other inventory holding and vehicle routing decisions over a specific planning horizon. We introduce constructive and improvement heuristic approaches for solving the problem with backorders, and benchmark it against lower and upper bounds found by a commercial software package, CPLEX.

The rest of this paper is organized as follows. In Section 2, we formulate the problem as a mixed integer linear program. The motivating ideas and search plan for the developed heuristics are presented in Section 3. Sections 4 and 5 provide descriptions of the constructive and improvement heuristics, respectively. In Section 6, the experimental results are presented followed by the conclusion and directions for future research in Section 7.

#### 2. Problem definition and mixed integer programming model

In the IRPB, we study a distribution system consisting of a 172 depot, denoted 0, and geographically dispersed customers, in-173 dexed 1,..., N. Each customer *i* faces a different demand  $d_{it}$  for 174 a single item per time period t (day/week). As traditionally con-175 sidered, a single item does not restrict the problem to the case 176 of a single product distribution, as the word 'item' can refer to 177 a unit weight or volume of the distributed products and each 178 customer can be viewed as a consumption center for packages 179 of unit weight or volume (Daganzo, 1999). Accordingly, the pro-180 posed model can be applied to the case of multiple products gi-181 ven that the values of the inventory holding and shortage costs 182 per unit volume/weight have small variance among the differ-183 ent products. We consider the case in which the demand of 184 each customer is relatively small compared to the vehicle 185 capacity, and the customers are located closely such that a con-186 solidated shipping strategy is appropriate. Deliveries to custom-187 ers  $1, \ldots, N$  are to be made by a capacitated heterogeneous fleet 188 of V vehicles, each with capacity  $q_v$  starting from the depot at 189 the beginning of each period. Vehicles must return to the depot 190 at the end of the period, and no further delivery assignments 191 should be made in the same period. In this model, we consider 192 the case in which renting additional vehicles during the short 193 planning horizon is not an option, and it is assumed that the 194 fleet of vehicles remains unchanged throughout the planning 195 horizon. 196

Each customer *i* maintains its own inventory up to capacity 197  $C_i$  and incurs inventory carrying cost of  $h_i$  per period per unit 198 and a backorder penalty (shortage cost) of  $\pi_i$  per period per 199 unit on the end of period inventory position. We assume that 200 the depot has sufficient supply of items that can cover all cus-201 tomers' demands throughout the planning horizon. The plan-202 ning horizon considers T periods. Transportation costs include 203  $f_{vt}$  a fixed usage cost for vehicle v, which depends on the period 204 t, and  $c_{ij}$  a direct transportation cost between *i* and *j*, which sat-205 isfies the triangular inequality. The objective is to minimize the 206 overall transportation, inventory carrying and backlogging costs 207 incurred over a specific planning horizon. We consider an inte-208 ger variable  $x_{iit}^{v}$ , which equals 1 if vehicle v travels from *i* to *j* in 209 period t, and 0 if it does not. The amount transported on that 210 trip is represented by  $y_{ijt}^{v}$ . At customer *i*, the inventory and 211 backorder at the end of time t is  $I_{it}$  and  $B_{it}$ , respectively. The 212 following is a mixed integer programming formulation for the 213 problem. 214

219 The objective function (0) includes transportation costs and 220 inventory carrying and shortage costs on the end of period inventory 221 position. Constraints Eq. (1) make sure that a vehicle will visit a loca-222 tion no more than once in a time period, and constraints Eq. (2) ensure route continuity. Constraints Eq. (3) serve for two purposes. 223 224 The first one is to ensure that the amount transported between two locations will always be zero whenever there is no vehicle mov-225 226 ing between these locations, and the second is to ensure that the 227 amount transported is less than or equal to the vehicle's capacity. 228 Constraints Eq. (4) along with the other elements of the model en-229 sure that efficient solutions will not contain subtours. We illustrate 230 in the Appendix A how this condition is achieved. Constraints Eq. (5) 231 are the inventory balance equations for the customers. Constraints 232 Eq. (6) limit the inventory level of the customers to the correspond-233 ing storage capacity. It is assumed that the amount consumed by 234 each customer in a given period is not kept in the customer's storage 235 location; accordingly, it is not accounted for in constraints Eq. (6). 236 Constraints Eqs. (7)–(10) are the domain constraints.

## 237 **3. Motivating ideas and heuristic design**

The IRPB is NP-hard since it includes the capacitated vehicle routing problem (VRP) as a subproblem. In this section, we present the key ideas in the proposed constructive and improvement heuristics for this NP-hard problem.

A key decision in solving the IRPB is the amount delivered to customer *i* in period *t*, as this quantity, let us define it by

$$w_{it} = \sum_{\nu=1}^{V} \left( \sum_{l=0}^{N} y_{lit}^{\nu} - \sum_{\substack{k=0\\l\neq i}}^{N} y_{ikt}^{\nu} \right) \ge 0, \text{ effectively separates the routing}$$

and inventory problems. In fact, given delivery values  $w_{it}$  for all

customers and periods, the inventory and backorder values are determined by constraints Eqs. (5)–(8). At the same time, the best routing solution for these  $w_{it}$  is obtained by solving *T* separate capacitated vehicle routing problems. Each VRP computes the optimal transportation costs to deliver  $W_t = (w_{it} : i = 1, ..., N)$  in period *t* by solving the following feasible problem whenever the delivery amounts satisfy 252

$$\sum_{i=1}^{N} w_{it} \leq \sum_{\nu=1}^{\nu} q_{\nu} :$$

$$TC_{t}(W_{t}) = \min \sum_{j=1}^{N} \sum_{\nu=1}^{\nu} f_{\nu t} x_{0jt}^{\nu} + \sum_{i=0}^{N} \sum_{\substack{j=0\\j \neq i}}^{N} \sum_{\nu=1}^{\nu} c_{ij} x_{ijt}^{\nu}$$
254

Subject to :

(5)

$$\sum_{j=0}^{N} x_{ijt}^{\nu} \leqslant 1 \qquad i = 0, \dots N \text{ and } \nu = 1, \dots V$$
(1')

$$\sum_{\substack{k=0\\k\neq i}}^{N} x_{ikt}^{\nu} - \sum_{\substack{l=0\\k\neq i}}^{N} x_{lit}^{\nu} = 0 \qquad i = 0, \dots N \text{ and } \nu = 1, \dots V$$
(2)

$$X_{ijt}^{\nu} - q_{\nu} X_{ijt}^{\nu} \leqslant 0 \qquad i, j = 0, \dots N, \quad i \neq j \text{ and } \nu = 1, \dots V$$
(3)

$$\sum_{\substack{l=0\\ l\neq i}}^{N} y_{lit}^{\nu} - \sum_{\substack{k=0\\ k\neq i}}^{N} y_{ikt}^{\nu} \ge 0 \qquad i = 1, \dots N, \text{ and } \nu = 1, \dots V$$
(4')

$$\sum_{\nu=1}^{\nu} \left( \sum_{\substack{l=0\\l\neq i}}^{N} y_{lit}^{\nu} - \sum_{\substack{k=0\\k\neq i}}^{N} y_{ikt}^{\nu} \right) = w_{it} \qquad i = 1, \dots N$$
(10)

$$x_{ijt}^{\nu} \ge 0 \quad \text{and} \quad x_{ijt}^{\nu} = 0 \text{ or } 1 \qquad i, j = 0, \dots N, \quad i \ne j \quad \text{and} \quad \nu = 1, \dots V$$

$$(11)$$

Therefore, the key in solving IRPB is to be able to identify the optimal delivery amounts  $w_{it}$  since what is left is a vehicle routing problem for which there exist several efficient algorithms. Our proposed heuristics build on this observation by focusing on how to determine the  $w_{it}$  variables efficiently. The procedure used to determine the  $w_{it}$  values must take into consideration the tradeoff existing between inventory and transportation costs.

In Section 4, we propose a constructive heuristic that sets the delivery amounts by balancing this tradeoff. The idea of the heuristic is to estimate a transportation cost value for each customer in each period from an approximate routing solution. Actual delivery amounts,  $w_{it}$ , are then decided by comparing these transportation cost estimates with the corresponding inventory costs. This process is done sequentially from the first period onward and in each period the comparison of transportation and inventory costs is done in two phases. The first phase looks into backorder decisions that are either imposed by insufficient vehicle capacity or preferred due to savings in transportation costs that are higher than backordering costs. The second phase investigates inventory decisions that would cover demand requirements in future periods in the case that excess vehicle capacity is available at the current period. The heuristic looks into inventory decisions that provide savings in future transportation costs that are higher than inventory carrying costs.

The improvement heuristic introduced in Section 5 investigates possible improvements to the solutions generated by the constructive heuristic by looking into modifications to the delivery quantities that would reduce transportation and/or inventory costs and result in overall cost savings. In particular the improvement heuristic relaxes the requirement made in the constructive heuristic to reduce the search space, that is all demand satisfied in a given period must be satisfied exactly not partially.

290 A key step in this heuristic is to be able to effectively estimate the transportation cost of each customer. Below we present a re-291 292 sult that provides insight into the structure of the total transporta-293 tion cost in period t as a function of the delivery amount  $W_t$ .

**Proposition 1.**  $\mathcal{I}C_t(W_t)$  is a multi-dimensional monotonic increasing 294 295 step *function*.

296 **Proof.** Given that the definition of  $TC_t(W_t)$  is based on an MIP model for the capacitated vehicle routing problem (VRP) in which 297 triangular inequality holds. Starting from an optimal solution of a 298 299 specific VRP at an initial  $W_t^0 = (w_{it}^0 : i = 1, ..., N)$ , and by adding  $\Delta W_t^+ = (\partial w_{it} : \partial w_{it} \ge 0, i = 1, ..., N)$  to  $W_t^0$  (i.e. increasing the 300 demand values for a subset of the customers) such that 301  $\sum_{i=1}^{N} (w_{it}^{0} + \partial w_{it}) \leq \sum_{\nu=1}^{V} q_{\nu}$ , one of two possible consequences will 302 occur: (1) new arc or arcs will be added to the current solution 303 to satisfy the vehicle capacity constraints Eq. (3), which will 304 increase  $TC_tW_t^0$  by the corresponding cij and/or ft amounts as 305 needed, or 2) the current VRP solution remains optimal. Thus 306  $TC_t(W_t + \Delta W_t^+) \ge TC_t(W_t)$ . Since the changes of  $TC_t(W_t)$  occur at 307 discrete points according to the vehicle capacities,  $T_{t}(W_{t})$  takes 308 309 the form of a multidimensional step function.  $\Box$ 

310 As a result of proposition 1, the solution scheme can focus 311 only on those values of the continuous variables,  $w_{it}$ , at which 312 changes to the transportation cost occur. We can look at this re-313 sult from another perspective. Given planned delivery amounts 314 to customers in a period, by reducing the delivery quantity of 315 a specific customer, the transportation costs will be reduced at discrete points and the maximum possible reduction will occur 316 317 when the delivery to that customer is dropped to zero. Although proposition 1 is proven for optimal solutions to the VRP, this re-318 sult can still be used for solutions generated by efficient heuris-319 320 tics as an approximation, such as the savings algorithm (Clarke & 321 Wright, 1964).

#### 4. Constructive heuristic 322

As mentioned earlier, the constructive heuristic is based on the 323 idea of estimating a transportation cost value for each customer in 324 325 each period, which is necessary to facilitate the comparison be-326 tween transportation and inventory carrying and shortage costs. We therefore refer to the constructive heuristic as the Estimated 327 Transportation Costs Heuristic (ETCH). In Subsection 4.1, we de-328 329 scribe how the transportation cost estimates are evaluated and 330 continuously updated throughout the course of the heuristic. Using 331 these estimates, we show in Subsection 4.2 how the inventory problem in IRPB can be decomposed into two subproblems that 332 are solved by the heuristic in two phases. The solution techniques 333 for these subproblems are illustrated in Subsection 4.3. 334

#### 335 4.1. Estimating transportation costs

Let  $w_{it}^{PL}$  be the planned delivery amount for customer *i* in period 336 t. For period  $\tau$  in which  $\sum_{j=1}^{N} w_{j\tau}^{p_L} \leq \sum_{\nu=1}^{V} q_{\nu}$ , let  $W_{\tau} = (w_{j\tau} : w_{j\tau} =$ 337  $W_{i\tau}^{PL}$ , j = 1, ..., N). For customer *i* whose  $W_{i\tau}^{PL} > 0$ ,  $let W_{\tau}^{(i)} = (w_{j\tau} : w_{i\tau})$ 338  $= 0, w_{j\tau} = w_{j\tau}^{PL}, j = 1, ..., N, j \neq i$ ). Then, the transportation cost reduc-339 340 tion that would result from reducing customer i's delivery in period  $\tau$  to zero can be calculated as  $TC_{\tau}(W_{\tau}) - TC_{\tau}(W_{\tau}^{(i)})$ . Since the 341 transportation cost function involves the solution of a VRP, which 342 343 is known to be NP-hard, it may not be possible to calculate its exact value, especially for large problem sizes. Instead, an efficient heu-344 ristic can be used to approximate it. In our implementation, the 345 346 savings algorithm is used for this purpose.

Let  $ATC_{\tau}(W_{\tau})$  be an approximation for  $TC_{\tau}(W_{\tau})$  when the savings 347 algorithm is used to solve the associated VRP. The transportation 348 cost estimate for customer *i* in period  $\tau$  is calculated as 349  $ETC_i(W_{\tau}) = ATR_{\tau}(W_{\tau}) - ATR_{\tau}(W_{\tau}^{(i)})$ . However, resolving a VRP every 350 time the transportation cost estimate for each customer is calcu-351 lated is in fact computationally inefficient. Instead, a faster approx-352 imation scheme can be constructed by evaluating the 353 transportation cost saving that will result when a customer is re-354 moved from its delivery tour assigned to it in a given VRP solution. 355 This means that for given delivery amounts,  $W_{\tau}$ , the associated VRP 356 will be solved only once and the resulting vehicle tours will be 357 used for generating transportation cost estimates. 358

 $ATC_t(W_t)$  and  $ETC_i(W_t)$  are functions of the planned delivery amounts  $w_{it}^{PL}$  which are determined based on the customers' net demand requirements in period t. However, the values of  $w_{it}^{PL}$  must be defined such that the vehicle capacity constraint,  $\sum_{i} w_{it}^{PL} \leq \sum_{i} q_{v}$ , is satisfied. Given the inventory position at the begin hing of period t,  $I_{i,t_{n-1}}$  -  $B_{i,t_{n-1}}$ , and the demand requirements  $d_{i\tau}$  for all periods  $\tau \ge t$ , ETCH evaluates the net demand requirement for each customer, and based on that it estimates  $w_{ir}^{PL}$ . If the vehicle capacity constraint is not satisfied in a given period, the  $w_{i\tau}^{PL}$  values are adjusted such that customers with the lowest unit shortage costs,  $\pi_i$ , will have part of their demand requirements postponed to future periods. The following list describes the steps of this approach.

Procedure PLNDLV(*t*)

- 1. Let OC = ordered set of all customers in which customers are sorted in a non-increasing order of their  $\pi_i$  values; 2. For every customer  $i \in OC$ , let  $inv_i = I_{i,t-1} - B_{i,t-1}$ ;
- 3. For period  $\tau_v = t$  to *T* do
- 4. Let  $Q^{\max} = \sum q_v$ ;
- 5. For every clistomer  $i \in OC$  using the order in set OC do
- 6.  $(w_{i\tau}^{PL} = \min(Q^{\max}, \max(d_{i\tau} inv_i, 0));$ 7.  $Q^{\max} = Q^{\max} w_{i\tau}^{PL};$

- 8.  $Inv_i = inv_i + w_{i\tau}^{PL} d_{i\tau}$ ;
- 9. End-Loop;

End-Loop; The resultant  $w_{i\tau}^{PL}$  values can be safely used in evalu-383 ating both functions  $ATC_{\tau}(W_{\tau})$  and  $ETC_i(W_{\tau})$ . During the course of 384 the algorithm, if a change in the delivery amounts occurs, a VRP 385 for the period in which the change occurred is instantiated and 386 solved to update the values of the transportation cost estimates. 387

#### 4.2. Problem decomposition and solution scheme

In the ETCH, the comparison between the transportation cost estimates and inventory carrying and shortage costs is separated into two subproblems that are solved sequentially. This comparison is conducted for every period t starting from the first period onward. The first subproblem is concerned with deciding whether to have backorders on period t and the second subproblem is concerned with deciding whether to use remaining vehicle capacity in period t, if any, to cover future customer demand.

Backorders can be profitable for two reasons; it is either cheaper to pay the backorder cost than the transportation cost, or there is insufficient capacity in the vehicles to satisfy demand. Let  $\delta_{i,t}$  = - $\max(d_{i,t} - I_{i,t-1} + B_{i,t-1}, 0)$  be the outstanding demand at customer *i* at the beginning of period t, and CD be the set of customers that have  $\delta_{i,t} > 0$ . The following subproblem decides whether to deliver to customer *i* in period *t* or not ( $z_i = 1$  or 0, respectively) and the quantity  $r_i$  to deliver such that the sum of backorder cost and estimated transportation cost is minimized and vehicle capacity constraints are satisfied.

411

$$\operatorname{Min} ATC_t(\Omega_t) + \sum_{i \in CD} \pi_i(\delta_{i,t} - r_i)$$

Subject to :

$$\sum_{i\in\mathcal{O}}r_i\leqslant\sum_{\nu=1}q_{\nu} \tag{12}$$

 $r_i = \delta_{i,t} z_i \quad \forall i \in CD$ (13) $\Omega_t = (\omega_{it} : \omega_{it} = r_i, i \in CD) \quad \forall i \in CD$ (14)

 $z_i = 0$  or  $1 \quad \forall i \in CD$ (15)

412 In SUB1, the objective function is composed of two parts, an 413 approximation of the transportation costs in period t and backor-414 der penalty costs. Both parts are functions of the decision variables 415  $r_i$ . Constraint (12) ensures that we do not exceed the total vehicle 416 capacity, and constraints Eq. (13) enforce that we deliver the exact amount of the outstanding demand only to customers included in 417 the delivery in period t. Constraint Eq. (14) defines the vector of 418 delivery amounts used in approximating the transportation cost 419 420 function.

421 The main outcome from solving SUB1 is the backorder decisions 422 evaluated as  $\underline{B}_{it} = \delta_{i,t}$  for every customer *i CD* that has  $z_i = 0$ , and 423 accordingly  $w_{it}$  = 0, in the solution of SUB1. The delivery amounts, 424  $w_{it}$ , for customers in set CD that have  $z_i = 1$  in the solution of SUB1 425 are not decided yet as future demand requirements may be added. 426 These decisions are investigated through subproblem SUB2. For every other customer *j* CD,  $w_{jt} = 0$ ,  $B_{jt} = 0$  and  $I_{jt} = I_{jt \ge 1} d_{jt}$ . 427

428 Let *FD* be the set of customers that have  $z_i = 1$  in the solution of 429 SUB1. Consider the integer variable  $u_{i\tau}$  to decide whether to deliver 430 customer *i*'s demand for period  $\tau$  in the current period *t*, where 431  $\tau > t$ . Let  $Q^r$  denote the total remaining vehicle capacity, i.e.

 $Q_r = \sum_{v=1}^{V} q_v - \sum_{i \in CD} r_i$ , and  $let T_i^{max}$  be the latest period where customer *i*'s demand can be considered without violating its storage capacity 432

433

constraint, i.e.  $T_i^{\max} = \min \left\{ \arg \max_L \left( \sum_{\tau=t+1}^L d_{i\tau} \leq C_i \right), T \right\}$ . We also define  $T_{\tau}^{\max} = \max_i (T_i^{\max})$ . 434 435

436 Let  $w_{i\tau}^{PL}$  be the planned delivery amount for customer *i* in a future period  $\tau > t$ . The values of  $w_{i\tau}^{PL}$  are initially calculated using 437 438 the PLNDLV(t + 1) procedure as described in <u>Subsection</u> 4.1 with 439 a small modification to make sure that for every customer  $j \in FD$ , initial values of  $w_{i\tau}^{p_L} = d_{jt}$ . If it is not possible to achieve this condi-440 tion in a future period  $\tau$  for customer  $j \in FD$ ,  $T_j^{\text{max}}$  is set to  $\tau - 1$ . The 441  $w_{i\tau}^{PL}$  values for customers that do not belong to set FD are fixed; 442 however, the values of  $w_{i\tau}^{PL}$  for customers in set FD change with 443 444 the change of the  $u_{i\tau}$  decision variables. The following problem de-445 cides whether to include future demand for any customer in the 446 current delivery by minimizing the total transportation and inven-447 tory costs and satisfying capacity limits. This part is formulated as 448 follows:

449 450

453

454

[SUB2] – Inventory decisions subproblem

$$\underset{\tau=t+1}{\text{Min}} \sum_{\tau=t+1}^{T_{\text{max}}^{\text{max}}} ATC(\Omega_{\tau}) \sum_{i \in FD} \sum_{\tau=t+1}^{T_{i}^{\text{max}}} [(\tau-t)h_i d_{i,\tau}] u_{i\tau}$$
Subject to :

$$\sum_{i \in FD} \sum_{\tau=t+1}^{T_i^{\max}} d_{i\tau} u_{i\tau} \leqslant Q^r \tag{16}$$

$$U_{i\tau-1} \ge u_{i\tau} \qquad \tau = t+1, \dots, T_i^{\max} \quad \forall i \in FD$$
(17)

$$W_{i\tau}^{PL} = d_{i\tau}(1 - u_{i\tau}) \qquad \tau = t + 1, \dots, T_i^{\max} \quad \forall i \in FD$$
(18)

$$\Omega_{\tau}(\omega_{i\tau}:\omega_{i\tau}=w_{i\tau}^{PL},i=1,\ldots,N) \qquad \tau=t+1,\ldots,T^{max}$$
(19)

Constraint Eq. (16) represents the available vehicle capacity limit.

For simplification, the customers' storage limits are represented

452 
$$U_{i\tau} = 0 \text{ or } 1 \cdot \tau = t + 1, \dots, T_i^{\max} \quad \forall i \in FD$$
 (20)

by the time index  $(T_i^{\text{max}})$ , which is computed in advance as 455 described earlier. The precedence constraints Eq. (17) are added 456 to represent the fact that future demand in a certain period is to 457 be considered only if the customer's preceding period demand is 458 fulfilled. Constraints Eq. (18) define the relationship between the 459 future planned delivery amounts for customers in set FD and the 460 decision variables  $u_{i\tau}$ . When the delivery amount in period t 461 changes, there may be changes in the transportation cost in that 462 period. The formulation of SUB2 neglects such changes.By solving 463 SUB2, the delivery amounts for customers in set FD can be calcu-464 lated as  $w_{it} = r_i + \sum_{\tau=t+1}^{T_i^{max}} d_{i\tau} u_{i\tau}$ . Accordingly, the inventory and 465 backorder decision variables in period t can be easily calculated. Fi-466 nally, delivery routes in period t are decided by solving a VRP using 467 the resulting delivery amounts. The flow chart in Fig. 1 summarizes 468 the major steps of the proposed heuristic. The following subsection 469 provides the algorithmic solutions for both subproblems and their 470 related analyses. 471

4.3. Solving subproblems

The two subproblems are resource allocation problems in which the scarce resource is the associated available vehicle capacity and the main decision variables,  $z_i$  and  $u_{it}$ , are binary variables. Accordingly, both of them can be solved optimally using dynamic programming (DP) as described in Taha (1992). However, with the increase of the problem size, mainly due to the number of customers and the planning horizon, the DP implementations suffer from the curse of dimensionality. In this section, we present efficient heuristics that can be used instead. First, we present the following result that characterizes optimal solutions to subproblem SUB1.

**Proposition 2.** There is an optimal solution to SUB1 that makes deliveries to customer i only if the quantity delivered satisfies  $r_i > ETC_i(\Omega_t)/\pi_i$  Also, every optimal solution to SUB1 only makes deliveries if  $r_i > ETC_i(\Omega_t)/\pi_i$ .

Proof. Assume that in the optimal solution to SUB1, some customer i is delivered ri that satisfies  $r_i > ETC_i(\Omega_t)/\pi_i$  or equivalently  $\pi_i(\delta_{i,t} - r_i) + ATR_t(\Omega_t) \geq \pi_i \delta_{i,t} + ATR_t(\Omega_t^{(i)})$ . If we consider the modified solution obtained by setting  $z_i = r_i = 0$ , then the previous inequality shows that the modified solution, which is feasible, is at least as good as the optimal solution. In the case when  $r_i > ETC_i(\Omega_t)/\pi_i$  then the modified solution is strictly better. Thus, the original solution cannot be optimal.  $\Box$ 

Proposition 2 gives a necessary condition for the optimality of the delivery decision made for a specific customer; however, satisfying this condition for all customers that have planned deliveries does not guarantee optimality for the solution of SUB1. Yet, since backorder decisions are generally not preferable, we will consider solutions that have this characteristic sufficiently good. We design the following algorithm that utilizes this rule.

Let  $DL_k = \{dl: dl \subseteq CD \text{ and } |dl| = |CD| - k\}$ , where |.| denotes the size of a set. We define  $\int^{SUB1}(dl)$  as the objective function value of subproblem SUB1 when  $z_i = 1$  for every customer  $i \in dl$  and  $z_i = 0$ for every customer  $j \in CD - dl$ , where  $dl \in DL_k$  for some k. If the vehicle capacity constraint of SUB1 associated with setting  $z_i = 1$ for all customers in a set *dl* is not satisfied, we define  $f^{SUB1}(dl) = \infty$ .The following list describes the steps of a breadth-first-based heuristic approach that searches for efficient solutions to SUB1.

Procedure SUBALG1

## 1. Let k = 0 and $dl^{\min} = CD$ :

2. If  $f^{\text{SUB1}}(dl^{\min}) \neq \infty$  and  $r_i \geq ETC_i(\Omega_t)/\pi_i \quad \forall i \in dl^{\min}$  then go to 9; 3. For every  $dl \in DL_k evaluatef^{SUB1}(dl)$ ;

- 6. Find  $dl^*$  from set  $DL_k$  that has the minimum  $f^{SUB1}(dl)$ ; tie-breaking is arbitrary
- 7. If  $f^{\text{SUB1}}(dl_*) < f^{\text{SUB1}}(dl^{\min})$  then let  $dl^{\min} = dl_*$ ;
- 8. If k < |CD| then let k = k + 1, go to 3;

 Génerate a solution for SUB1 in which deliveries are only made to customers in set dl<sup>min</sup>;

SUBALG1 evaluates the  $f^{\text{SUB1}}(dl)$  value for every set  $dl \in DL_k$  at values of k = 0, ..., |CD|. If at some level of k, the condition that  $r_i > ETC_i(\Omega_t)/\pi_i$  is satisfied for all  $i \in dl$ , we find an approximate solution and the algorithm terminates. However, if steps 2, 4 and 5 are removed, the algorithm guarantees that an optimal solution for SUB1 has been identified.

Subproblem SUB2 can be illustrated graphically. Consider the 534 sample case for SUB2 illustrated in Fig. 2. The decision variables 535 536  $u_{i\tau}$  are represented by directed arcs, where the cost saving associated with each arc  $S_{i\tau-t} = ETC_i(\Omega_{\tau}) - (\tau - t)h_i d_{i\tau}$ . A solid vertical line is drawn to represent the time limit  $T_i^{\text{max}}$  for customer *i*. Start-537 538 ing from node 0, arcs are to be selected using the order given by 539 their directions, such that the total cost saving is maximized and 540 the vehicle capacity constraint is satisfied. We note here that if 541 one or more arcs in a given period are selected, the saving values 542 543  $S_{i\tau-t}$  of the unselected arcs in the same period will be changed 544 due to changes in the transportation cost estimates and therefore 545 have to be recalculated.

Inspired by this graphical representation, subproblem SUB2 546 can be dealt with as precedence constrained knapsack problem 547 (PCKP) in which the coefficients of the objective function,  $S_{j\chi-t}$ , 548 are dependent on the decision variables. The PCKP is known to be NP-hard (Garey & Johnson, 1979); however, Johnson and Niemi (1983) provide a dynamic programming algorithm for the PCKP that can solve the problem in a pseudo-polynomial time, given that the underlying precedence graph is a tree, which is fortunately a property of SUB2 as can be seen in Fig. 2. 555

We present here a simpler algorithm based on a greedy search that selects the next possible arc (see Fig. 2) that has the maximum positive saving. This algorithm does not guarantee optimality to the solution of SUB2; however, it can produce relatively good solutions in polynomial time. The following steps describe the algorithm.

| Procedure SUBALG2   | 562 |
|---|-----|
| 1. Let $D^{\max} = Q^r$ and $TD = \frac{FD}{FD}$ ;  | 564 |
| 2. For every customer i in set TD, Let $\Delta t_i = 1$ ;   | 565 |
| 3. Find customer j in set TD that has the largest positive value of                                 | 566 |
| $(ETC_i\Omega_{t+\Delta t_i}) - \Delta t_i h_i d_{i,t+\Delta t_i})$ ; If none found then terminate; | 567 |
| 4. If $D^{\max} \ge d_{i,t+\Lambda t_i}$ then   | 568 |
| Let $D^{\max} = \overline{D}^{\max} - d_{i,t+\Delta t_i}$ ;   | 569 |
| Add $d_{i,t+\Delta t_i}$ to customer j's delivery amount and  | 570 |
| updatetransportation cost estimates in period t+ $\Delta t_i$ ;                                     | 571 |
| Let $\Delta t_i = \Delta t_i + 1$ ;   | 572 |
| If $\Delta_i > T_i^{\text{max}}$ then remove customer j from set TD;                                | 573 |
| End-If  | 574 |
| Else remove customer <i>j</i> from set <b>TD</b> ;  | 575 |
| 5. If $TD = \emptyset$ then terminate: Else go to step 3.   | 576 |

Fig. 2. Graphical illustration of subproblem SUB2 for a sample case.

# 579 **5. Improvement heuristic**

580 There are two apparent limitations of ETCH. The first is due to 581 the myopic nature of the decisions conducted. This myopic nature 582 stems from the strategy used at each period for solving the two 583 subproblems, as it aims to optimize inventory allocation decisions at the studied period without considering the impact of such deci-584 585 sions on the optimality of the overall solution. The second limita-586 tion is concerned with not allowing for partial fulfillment of 587 demand, that is exact demand requirements in the current and future periods must be considered in the delivery schedule. This may 588 prevent ETCH from achieving further savings, especially in trans-589 portation and backordering costs. To overcome these limitations, 590 591 we introduce in this section an improvement heuristic. In this heuristic, transitions from a given solution to its neighborhood are 592 593 conducted using the idea of exchanging customers' delivery 594 amounts between periods. These delivery exchanges are conducted 595 through guiding rules that tend to reduce the total cost.

#### 596 5.1. Neighborhood search structure

597 First, we define in this section a neighborhood search structure to be used in the developed improvement heuristic. The act of 598 599 reducing a customer's delivery in a given period t and adding the 600 reduced amount to another period is referred to as delivery ex-601 *change*. If a delivery exchange is made to period  $\tau < t$ , it is referred to as backward delivery exchange. In this case, there may be an in-602 603 crease in the inventory carrying cost for the customer or a reduc-604 tion in backordering cost when a backorder exists in a preceding 605 period to which the transferred amount is added. A forward delivery exchange occurs when a delivery exchange is made to period 606 607  $\tau > t$ . In this case, either a reduction in the inventory carrying cost 608 will be gained or a shortage cost will be incurred depending on the amount exchanged. A forward delivery exchange may be needed to 609 610 create more capacity in period t, which could be more profitable for other customers' backward delivery exchanges. 611

612 Let  $\hat{w}_{i,t \to \tau}$  denote the amount of delivery exchange made from 613 period t to period  $\tau$  for customer i. Let  $\Delta IC(\hat{w}_{i,t\to\tau})$  represent the 614 overall change in inventory carrying and shortage costs (positive if increased) associated with the delivery exchange  $\hat{w}_{i,t\to\tau}$ . From 615 Proposition 1, we know that the reduction (increase) of the deliv-616 617 ery amount made to a specific customer is associated with either 618 reduction (increase) in the transportation costs or the transporta-619 tion costs remain unchanged. Let  $TCR_t(\hat{w}_{i,t\to\tau})$  and  $TCI_\tau(\hat{w}_{i,t\to\tau})$  denote, respectively, the amounts of transportation cost reduction in period *t* and the transportation cost increase in period  $\tau$  that will result from a delivery exchange  $\hat{w}_{i,t} \rightarrow \tau$ . By using backward and forward delivery exchanges, a transition from an incumbent solution to its neighborhood can be achieved.

A single delivery exchange may not be profitable, yet a combination of delivery exchanges, applied in a specific sequence, can lead to a reduction in the total cost. Generally, a better solution can be obtained by searching for an ordered set of exchanges, *DX*, that maximize the resultant cost saving  $\sum_{\hat{w}_{i,t} \to \tau^{aDX}} TCR_t(\hat{w}_{i,t \to \tau}) TCl_{\tau}(\hat{w}_{i,t \to \tau}) - \Delta IC_{\tau}(\hat{w}_{i,t \to \tau})$  while maintaining the vehicle and customer capacity constraints. The following subsection discusses some of the guiding rules that can use for this purpose.

#### 5.2. Guidelines for delivery exchanges

For a given solution, the first step in constructing useful delivery exchanges is to look for reductions to the delivery amounts at a selected period so that savings in transportation costs in that period can be achieved, and additions of delivery amounts to customers that have backorders at the end of that period such that their associated shortage costs is reduced.

In Proposition 1, it is shown that the reduction in transportation costs as a result of reducing the delivery amount to a customer occurs at discrete values of the amount reduced. The reason for such discrete changes is due to changes in the vehicle tours which are directly related to the usage of vehicle capacities. Therefore, reductions to delivery amounts that will result in reducing transportation cost can be determined by studying the relationship between the total delivery amount and the vehicle capacities. In the case when there is a backorder decision for a customer in a given period, reduction to shortage costs can be achieved by increasing the delivery made to the customer. The amount of increase is bounded by the total amount of backorder. In this case backward delivery exchanges from future periods are needed.

After deciding the suitable amounts of delivery reduction and addition, the next step is to select the mechanism by which the reduced or added amount can be exchanged to or from another period (the ordered set of delivery exchanges) such that reduction in the total cost can be achieved. Abdelmaguid and Dessouky (2006) list a set of different delivery exchange rules that can be used to effectively guide a neighborhood search algorithm. These rules are adopted here for the developed improvement heuristic.

#### 662 5.3. The improvement heuristic

13 October 2008 Disk Used

663 The developed improvement heuristic can be considered as a 664 complementary phase to ETCH in which partial fulfillments of 665 demand and their associated cost reductions are investigated. Con-666 trary to ETCH, the improvement heuristic conducts its iterations 667 starting from period *T* backward to period 1. The reasons for such backward movement is to provide a remedy for the myopic deci-668 669 sions of ETCH. In its search for the best ordered set of delivery 670 exchanges, the improvement heuristic employs the previously described delivery exchange rules repeatedly at a given period in 671 672 a systematic fashion. We refer to the improvement heuristic as the Backward Delivery Exchanges Heuristic (BDXH). The following 673 list describes its main steps. 674

Procedure BDXH

676 1. Let  $s^*$  be the initial solution obtained by ETCH;

677 2. Let t = T;

678 3. Let set  $\$1 = \$s^*$  and set  $\$2 = \emptyset$ ;

679 4. For every solution in set S1 do

- 4.1. Let *R* represent the set of customers that either havescheduled deliveries or backorders in period t.
  - 4.2. For each customer *i* in set *R* find all possible reductions/ additions  $(\Delta w_{it})$  to the delivery amount of customer *i* in which either a transportation cost saving or a reduction in the shortage cost can be achieved.
    - 4.3. For every possible  $\Delta w_{it}$  found in step 4.2, generate suitable delivery exchanges for that amount in period *t* using the delivery exchange rules described earlier
  - 4.4. Generate all the resulting neighborhood solutions for the delivery exchanges found in step 4.3, and add them to set \$2 such that solutions are stored in an increasing order of their costs and solutions are not repeated. If the allowed maximum size of set \$2 is exceeded, solutions with the worst costs are eliminated
- 696 5. If the cost of the best solution in set  $\frac{52}{2}$  is less than the cost of  $\frac{5}{5}$ , 697 then let  $\frac{5}{5}$  be that solution
  - 6. Let 51 = 52, repeat step 4 until there is no further delivery exchanges in period *t* that can be made
  - 7.Let t = t 1, if t > 0 then go to step 3, otherwise STOP. The best solution found is  $s^*$ .

The most time consuming part of the BDXH is the generation of the neighborhood solutions in step 4.4, as a vehicle routing problem has to be solved for every period in the planning horizon in which a change in the delivery schedule occurs. The loop conducted in step 4 has a polynomial time complexity that is a function of the maximum size allowed for set *S*2. In the conducted experiments this maximum size is selected to be twice the number of customers.

### 710 6. Experimentation and results

Two versions of ETCH have been implemented. In the first one, 711 712 optimal solutions for the two subproblems are generated using a 713 complete breadth-first search for SUB1 and a dynamic programming 714 algorithm for SUB2. We refer to this implementation as ETCH-O. The second version uses the provided breadth-first heuristic for SUB1 715 716 and the greedy-search algorithm for SUB2, and is referred to as 717 ETCH-H. The improvement heuristic is then applied using the initial 718 solutions generated by each version of ETCH. Accordingly, we refer 719 to the results obtained by the improvement heuristic as BDXH-O 720 and BDXH-H depending on the initial solution used. These heuristics 721 are programmed and compiled using Borland C++ Builder version 3

and benchmarked against the lower and upper bounds obtained by722AMPL-CPLEX 8.1 running under an Intel Pentium 4 processor running with a clock speed of 2.40 GHz with 1GB RAM.723

#### 6.1. Experimental design

First, we consider two different scenarios to examine the effectiveness of the developed heuristics under different circumstances. These scenarios simulate the integrated inventory-distribution decisions faced by manufacturing companies that deal with small number of customers, each located in a different major city. An example for similar cases in the literature can be found in Fumero and Vercellis (1999).

The first scenario is designed to test the quality of the inventory holding decisions of ETCH; while, in the second one, some parameters are tuned to provide conditions in which backorder decisions are economical, so that the backorder decisions of the ETCH are assessed. The main factors that are controlled to produce such cases are the ratio of the available vehicle capacity to the average daily demand by customers, the average unit shortage cost and the transportation cost per unit distance.

In both scenarios, customers are allocated in a square of  $20 \times 20$  distance units and their coordinates are generated using a uniform distribution within these limits. The depot is located in the middle of the square. Customers' unit holding costs are generated using a normal distribution with a mean of 0.1 and a standard deviation of 0.02, and each customer has a storage capacity of 120 items. A constant value of 10 for the vehicle usage cost ( $f_{vt}$ ) is used.

In the first scenario, the transportation cost per unit distance is 748 set to 1, the customers' unit shortage costs are generated using a 749 normal distribution with a mean of 5 and a standard deviation of 750 0.5, and the customers' demands are generated using a uniform 751 distribution from 25 to 50 items per day. In the second scenario, 752 we set the parameter values so it is optimal to carry backorders. 753 In this scenario, the transportation cost per unit distance is set to 754 2, the customers' unit shortage costs are generated using a normal 755 distribution with a mean of 3 and a standard deviation of 0.5. and 756 the customers' demands are generated using a uniform distribu-757 tion from 5 to 50 items per day. 758

For each scenario, sixty problems have been generated by varying the number of customers (N), the number of planning periods (T) and the number of homogenous vehicles (V). We generate three levels of N(5), (10), and (15), two levels of T(5) and (7), and two levels of V(1) and (2). For each problem setting defined by a combination of N, T, and V, we randomly generate five problems. The total vehicle capacity in the first scenario is selected to be fixed at 500, 1000, and 1500 for each level of N, respectively. In the second scenario, the selected total vehicle capacities are 150, 300, and 450.

The naming convention used for the test problems starts with a number that refers to the scenario. After a hyphen, two digits are assigned for the number of customers, followed by a digit representing the length of the planning horizon. The next digit represents the number of vehicles. Finally, the replicate number is given at the last digit after a hyphen. Thus, the problem 1-0551-1 represents the first replicate of the first scenario with 5 customers, a planning horizon of 5 periods and 1 vehicle.

#### 6.2. Results and discussion

784 The percentage differences between the total cost obtained by 785 each heuristic and the lower bound are used as performance indi-786 cators. The percentage difference, also referred to as optimality gap, is calculated by taking the ratio of the difference between 787 the heuristic's total cost and the lower bound to the lower bound. 788 A comparison against the lower bound provides a measure of 789 790 deviation from optimality. The CPLEX upper bound in a maximum 791 of one-hour running time is used as an alternate heuristic and its 792 percentage difference against the lower bound is similarly 793 calculated.

For each problem setting, the average of the percentage differences of the 5 replicates is calculated and plotted against the number of binary variables of that setting as shown in Fig. 3 and 6. Table 1 summarizes the average computational time of the developed heuristics for each problem set in both scenarios.

799 As shown in Figs. 3 and 4, the combined constructive and improvement heuristics outperform the CPLEX upper bound for in-800 801 stances with ten customers and more in the first scenario and 15 802 customers in the second scenario. While the growth of the CPLEX 803 optimality gap seems to be exponential with the increase of the 804 number of binary variables, the optimality gap for the developed 805 heuristics is below 30% on average and remains almost level with 806 the increase of the number of binary variables.

In the first scenario, the ETCH-O version of the constructive heuristic is on average 2% closer to the lower bound than ETCH-H. However, after applying the improvement heuristic on both versions this difference reduces to only 0.4%. In the second scenario, this difference is 1% and slightly increases with the application of the improvement heuristic to 1.25%.

Reductions to the total cost as a result of applying the improvement heuristic are evident. In the first scenario the improvement heuristic provides reductions in the optimality gap of 6.1% and 7.7% on average over solutions generated by ETCH-O and ETCH-H, respectively. While in the second scenario, these figures are 4% and 3.8%, respectively.

In the case of small problem instances of 150 and 210 binary variables, for which CPLEX was able to find optimal solutions within the one-hour time limit, we can see that the improvement heuristic can reach a relatively good optimality gap of less than 1% in the case of 150 binary variables and less than 5% for the case of 210 binary variables for the first scenario problems. These figures are higher in the case of the second scenario problems. However for larger problem instances, it is hard to judge the quality of the lower bounds obtained by CPLEX, and so the optimality gaps obtained can not give a clear cut measure of how far the results obtained by the developed heuristics are from the optimal solutions.

The computational time for ETCH-H is found to be less than one second in all the cases tested. For ETCH-O, due to the dynamic programming part of the algorithm, the computational time increases with the increase of the problem size; however on average, it has not reached the 90 seconds limit in all problem sets. The increase of computational time of ETCH-O is mostly attributed to the increase in both *N* and *T*; while, the number of vehicles, *V*, does not seem to have a significant effect on computational time. The computational time of the improvement heuristic seems to increase at a higher rate with the increase of the problem size in the first scenario as compared to the second one. We attribute this to the increase of the ratio of the total vehicle capacity to the average daily customers' demand, which increases the number of possible delivery exchanges and neighborhood solutions generated at each iteration of BDXH.

From the previous results we conclude the following. The ETCH-O version of the constructive heuristic is capable of generating slightly better solutions compared to ETCH-H with up to 2% difference on average in the optimality gap. However, with the increase of the problem size, especially the number of customers and the number of planning periods, the computational time of ETCH-O will be significantly higher than the computational time of ETCH-H. H. The consideration of partial fulfillment of demand and the mechanism of delivery exchanges implemented by the improvement heuristic seem to offer improvements to the optimality gap that can reach more than 3.8% on average. However, the computational time of BDXH will be considerably higher with the increase of the ratio between vehicle capacity and the average customers demand per period.

#### 6.3. Experimental results for larger problem instances

To investigate the performance of the developed heuristics with larger problem sizes, we construct an additional experimental set based on a third scenario. In this scenario, medium vehicle capacity to average daily demand ratio is used such that a situation in the middle of the first two extreme scenarios is addressed. This scenario considers similar parameters as in the second one with some modifications to reduce the frequency in which backorder decisions are needed. The main difference between the parameters

used in the third scenario as compared to the second one is that the travel cost per unit distance is set to 1 and customers daily demand is generated using a uniform distribution between 0 and 25. We consider three different levels of the number of customers, N: 20, 25, and 30, and a total vehicle capacity of 300, 350, and 400 at each level of N, respectively. We only consider one level for both Tand V at 7 and 2, respectively. Five random replicates are generated at each level of N. We use the previously defined naming convention for the third scenario problems. The detailed cost results for the third scenario problems are

The detailed cost results for the third scenario problems are shown in Table 5 in the Appendix A. CPLEX lower and upper bounds are obtained after a running time of three hours. Due to the inability of the optimization routines to find solutions for the two subproblems for these large problem instances, we only ran the heuristic versions, ETCH-H and BDXH-H. The average cost and time results for the ETCH-H version and the improvement heuristic BDXH-H are shown in Table 2.

We can see that the rate of increase of the heuristics optimality gaps is almost constant with the increase of the number of customers. When we compare this with the exponential rate of increase for the CPLEX upper bound percentage difference, we can see the potential benefit of the developed constructive and improvement heuristics for larger problem sizes. In terms of computational time, the ETCH-H version of the constructive heuristic remains below one second for larger problems with up to 30 customers; while, the improvement heuristic has an increasing computational time.

#### 7. Conclusion and future work

This article addressed the inventory routing problem with backlogging in which multiperiod vehicle routing and inventory holding and backlogging decisions for a set of customers are to be made. We considered an environment in which the demand at each customer is relatively small compared to the vehicle capacity, and the customers are closely located such that a consolidated shipping strategy is appropriate. We presented a constructive heuristic based on the idea of allocating single transportation cost estimates for each customer. Two subproblems, comparing inventory holding and backlogging decisions with these transportation cost estimates, are formulated and their solution methods are incorporated in the developed heuristic. The main idea behind the constructive heuristic as seen in the formulation of the two subproblems is to consider only delivery plans in which fulfillment of part of the current or the future demand requirements in a currently studied period is not allowed. An improvement heuristic is developed to overcome some of the limitations of the constructive heuristic. This improvement heuristic is based on the idea of exchanging delivery amounts between periods to allow for partial fulfillments of demands and exploit associated reductions in costs. A mixed integer programming formulation is provided and used to obtain lower and upper bounds using AMPL-CPLEX to assess the performance of the developed heuristics.

For small sized problems with up to 15 customers, the experimental results show that the developed constructive heuristic can achieve solutions that are on average not farther than 30% from the optimal in a few minutes. This figure can be reduced to 25% by applying the improvement heuristic which shows the significance of allowing partial fulfillment of demand. With the increase of problem size, the optimality gap of the developed heuristics increases with almost a constant rate and results can be obtained in a few minutes. This shows the potential benefit of the developed heuristics for larger problem sizes.

The studied problem and the developed heuristic approaches can give insights for solving other problems in the manufacturing

T.F. Abdelmaguid et al. / Computers & Industrial Engineering xxx (2008) xxx-xxx

industry that have wider scope. The integration of manufacturing 933 and logistic decisions at the operational planning level, as found 934 in Chandra and Fisher (1994), Fumero and Vercellis (1999) and 935 Lei, Liu, Ruszczynski, and Park (2006), is a good example of one 936 937 such problem.

#### Appendix A. Appendix

### A.1. An illustration of the subtour elimination mechanism in the developed MILP model

To illustrate the role of constraints Eq. (4) in eliminating sub-941 tours in the proposed MILP model, let us start with an MILP model 942 for the IRPB that does not contain constraints Eq. (4) and call it 943 IRPB<sup>-(4)</sup>. Consider a case in which there is only one vehicle and 944 three customers. Then, constraint Eq. (5) can be rewritten as 945 follows:

$$\sum_{\substack{l=0\\l\neq i}}^{3} y_{lit}^{1} - \sum_{\substack{k=0\\k\neq i}}^{3} y_{ikt}^{1} = d_{it} - I_{it-1} + B_{it-1} + I_{it} - B_{it}$$

$$i = 1, \dots, 3 \quad \text{and} \quad t = 1, \dots, T \quad (21) \quad 948$$

The right-hand-side of the above equation represents the 949 amount that will be delivered to customer *i* in period *t*. Let us de-950 note this quantity by  $\varsigma_{it}$ . Notice that  $\varsigma_{it}$  is unrestricted in sign since 951 constraints Eq. (4) are excluded. Let us consider one time period 952 and let us drop the indexes for both the time period and the vehicle 953 for brevity. Then, the above equation is reduced to: 954

$$\sum_{\substack{l=0\\i\neq i}}^{3} y_{li} - \sum_{\substack{k=0\\k\neq i}}^{3} y_{ik} = \varsigma_i \qquad i = 1, \dots, 3$$
(22)

The above equation is quite familiar in network flow models as it is equivalent to saying that the difference between the amount of inflow and the amount of outflow to and out of node *i* equals the quantity delivered to that node. Now, let us consider a simple numerical example in which  $\varsigma_1 = 2$ ,  $\varsigma_2 = -5$  and  $\varsigma_3 = 3$ . Fig 5(a) illustrates one feasible vehicle tour for this case that satisfies all the vehicle routing constraints of IRPB<sup>-(4)</sup>, yet it contains the subtour 1-2-3-1.

Notice that constraints Eq. (4) are non-negativity constraints for the delivery quantities  $\varsigma_i$  which when added to the MILP model we would not obtain a negative value for  $\zeta_2$ . The two feasible vehicle tours illustrated in Fig. 5(b) and (c) represent two different feasible solutions when the value of  $\varsigma_2$  equals zero and greater than zero, respectively. Based on the required delivery quantities  $\varsigma_1$ ,  $\varsigma_2$ , and  $\varsigma_3$ , the values for the continuous variables  $y_{ij}$  will be determined as required by constraints Eq. (5), which in turn will force the binary decision variables  $x_{ii}$  to take the value of one as necessitated by constraints Eq. (3). Accordingly, new arcs will be added to the vehicle tour, which in turn must satisfy constraints Eq. (1) and (2). It can be easily shown that the subtour 1-2-3-1 in both cases shown in Fig. 5(b) and (c) can not occur, for otherwise constraints Eq. (1) and (2) will be violated. This logic can be easily extended for the case of more than one vehicle.

Furthermore, for the cases in which nodes  $(o_1, o_2, \dots, o_N)$ have zero delivery quantities, subtours that come in the form  $o_1 - o_x - \ldots - o_1$  would not be efficient since an additional unnecessary transportation cost associated with the their arcs will be added.

From the above analysis, It is evident that constraints Eq. (4) which mandates that the quantity delivered to any node by a given vehicle should be greater than or equal to zero is necessary for eliminating subtours in the developed MILP model.
